Disk Scheduling In Real Time Database Systems

Uma Shanker Jayswal* Gaurav Kumar Jain** Ravi Ranjan***

ABSTRACT

In The Information age, information spreading worldwide through Internet, and Other medium, is bulk and changing constantly and dynamic in nature. As Your society becomes more integrated to computer technology, Information proceed for human activities necessitates computing that responds to request in real time rather than just with best effort. In fact Database management systems have entered the internet age. If too many users approach for information, than this degrades the system performance. The degradation may cause delay and trouble for particular end user in assessing the information. Assessing Information in easy way and within certain time limit by keeping its freshness, assessing users requirements and then providing them Information in time is important aspect.

Conventional databases are mainly characterized by their strict data consistency requirement. Database systems for real time applications must satisfy timing constraints associated with transactions. The main objective of this paper is to initiate an enquiry in disk scheduling for real time database systems. The proposed work implements the algorithms for disk scheduling for real time database systems.

GENERAL PARAMETERS CONSIDER FOR ALGORITHM DEVELOPMENT:
Deadline: Time by which execution of the task should be Completed, After the task is released
Arrival Time: Arrival Time of transactions
Inter Arrival time
Average Execution time
Transaction Size
Slack Time: is an estimate of how long we can delay the execution of transaction and still meet its deadline
Access Time: Access time =Seek Time+ Rotation latency +Transfer Time
Where, Seek Time is the time for the disk to move the heads to the cylinder containing the desired sector.
Rotation latency is the time waiting for the desk to rotate the desired sector to the disk head.
Transfer time is the transfer time needed to transfer data over the IO bus.
Priority: priorities can be assign by two ways .
Earliest Deadline: the transaction with the earliest deadline has the highest property. A major weakness of the police is that it can assign the highest property to task that already has missed or is about to miss its deadline
Least Slack: Slack time is an estimate of how long we can delay the execution of transaction and still meet its deadline. If s>=0 than we accept that if transaction is executed without interruption then it will finish at or before its deadline. Negative slack time results either when a transaction has already missed its deadline or when we estimate that it can note meet its deadline. The slack time of a transaction which is not executing decreases .hence the priority of that transaction increases.

Real-Time Disk Scheduling Algorithms: The real time disk scheduling algorithm like earliest Deadline First (EDF), Priority scan (P-scan)-feasible deadline scan (FD-Scan), Shortest seek and earliest deadline by ordering (SSEDO) and shortest seek and earliest deadline by value (SSEDV) are discussed in brief here.

EDF Algorithm: The earliest deadline first algorithm is an analog of FCFS .Requests are ordered according to deadline and the request with to the earliest deadline serviced first. Assigning priorities transactions an earliest deadline

Policy minimizes the number if late transactions in systems operating under low or moderate levels of resource and data contention. This is due to Earliest Deadline giving the highest priority to transactions that have the least remaining time in which to complete. However, the performance of Earliest
Deadline steeply degrades in an overloaded system [3]. This is because, under heavy loading, transactions gain high priority only when they are close their deadlines. Gaining high priority at this late stage may not leave sufficient time for transactions to complete before their deadlines. Under heavy loads, then, a fundamental weakness of the Earliest Deadline priority policy is that it assigns the highest priority to transactions that are close to missing their deadlines, thus delaying other transactions that might still be able to meet their deadlines [1].

**P-SCAN ALGORITHM**

In priority Scan (P-Scan) all request in the I/O queue are divided into multiple priority level, which means that the disk serves any requests that is passes n the current served priority level until there are no more requests in that direction. On the completion of each disk service, the scheduler checks to see whether a disk service, the scheduler checks to see whether a disk request of a higher priority is waiting for service [4]. If find, the schedule switches to that higher level. In this case, the request with shortest seek distance from the current arm position is used to determine the scan direction. All the I/O requests are mapped into three priority levels according to their deadline information. Specially, transactions relative deadlines are uniformly distributed between LOW_DL and UP_DL, where LOW-DL and UP-DL are lower and upper bound for transaction deadline settings. If a transactions relative deadline is greater than (LOW_DL +UP_DL) /2, then the transaction is assigned a middle priority [2].

**FD-SCAN ALGORITHM**

In FD-Scan, the track location of the request with earliest with earliest feasible deadline is used to determine the scan direction. A deadline is feasible if we estimate that it can be met. More specially, a request that is n tracks away from the current head position has a feasible deadline d if d >= t+ Access(n) where t is the current time and Access(n) is a function that yields the expected time needed to service a request n tracks away. Each time that a scheduling decision is made, the read requests are examined to determine which have feasible deadlines given the current head position. The request with the earliest feasible deadline is the target and determines the scanning direction. The head scans toward the target servicing read requests along the way. These requests either have deadline, later than the target request or have unfeasible deadlines, ones that cannot be met. If there is no read request with a feasible deadline, then FD-SCAN simply services the closest read request. Since all request simply services the closest read request. Since all request deadlines have been (or will be) missed, the order of service is no longer important for meeting deadlines [4].

The SSEDO and SSEDV Algorithms re based on the following Assumptions:

Let, ri: be the I/O request with the i-th smallest deadline at a scheduling instance;
Di: be the distance between the current arm position and requests ri’s positioning;
Li: be the absolute deadline of ri [2] [5].

The two algorithms maintain a queue sorted according to the absolute deadline, Li, of each request in the queue, i.e., the window consists of m request with smallest deadline.

**SSEDO ALGORITHM**

At a scheduling instance, the scheduler selects one of the request from the window for service. The scheduling rule is to assign each request a weight, say wi for request ri, where w1 = 1, +w2 <=....wm and m is the window size, and to choose one with the minimum value of widi. We shall refer to this quantity widi as the priority value associated with request ri. If there is more than on request with the same priority value, the one with earliest deadline us selected. It should be clear that for any specific request, its priority value varies at each scheduling instances, since di, ri’s position with respect to disk arm position, is changing as disk arm moves.

The idea behind the above algorithm is that we want to give requests with smaller deadlines higher priorities so that they can receive service earlier. This can be accomplished by assigning smaller values to their weights. On the other hand, when a request with large deadline is “Very” close to the current arm position
(which means less service time), it should get higher priority. This is especially true when a request is to access the cylinder where the arm is currently positioned. Since the cylinder where the arm is this case and we are assuming the seek time dominates the service time, the service time can be ignored. Therefore these requests should be given the highest priority. There are various ways to assign these weights. The weights can simply set to \( w_i = \beta^{-1} \) (\( \beta \geq 1 \)) \( I = 1,2,3,\ldots,m \).

where \( \beta \) is an adjustable scheduling parameter. Note that \( w_i \) assign priority only on the basis of the ordering of deadlines, not on their absolute or relative values [2].

**SSEDV Algorithm**

In the SSEDV algorithm described above, the scheduler uses only the ordering information of request deadlines of successive requests in the window. For example, suppose there are two requests in the window, and \( r_1 \)'s deadline is very close but \( r_2 \)'s deadline is far away. If \( r_2 \)'s position is “very” close to the current arm position, then the SSEDV algorithm might schedule \( r_2 \) first, which may result in the loss of \( r_1 \). However, if \( r_1 \) is scheduled first, then both \( r_1 \) and \( r_2 \) might be served. On the other extreme, if \( r_2 \) deadline is almost same as \( r_1 \)'s and the distance \( d_2 \) is less than \( d_1 \) but greater than \( d_1/\beta \), then SSEDV will schedule \( r_1 \) for service and \( r_2 \) will be lost. In this case, since there could be loss any way, it seems reasonable to serve the closer one (\( r_2 \)) for its service time is smaller. Based on these considerations, we expect that a more intelligent scheduler might use not only the deadline ordering information but also the deadline value information for decision making. This leads to the following algorithms: associate a priority value of \( \alpha \) (\( 0 \leq \alpha \leq 1 \)) is a scheduling parameter.

A common characteristic of SSEDV and SSED0 algorithm is that both consider time constraints and disk service times. Which part play the greater role in decision making can be adjusted by tuning the scheduling parameters \( \alpha \) or \( \beta \), depending on the algorithm [2] [5].

1. **EDF Algorithm Design:**
   1) Sort transaction on deadline in increasing order. [repeat step 2 and 3 till no more transactions in queue]
   2) [set start time, end time, seek time. Current head position, total transaction time, turn around time for all the transactions in the queue]
      a) For all transactions set start time = actual arrival time
      b) For all transaction set the following parameters set start time = end time [except first transaction set seek time = blocked accessed - current head position

      Set total transaction time = seek time + transmission time
      Set end time = start time + total transaction time set turn around time = end time – actual arrival time
   3) [check transaction is miss or hit]
      If (end Time > deadline) Set successful = false else set successful = true end if
   4) Exit

2. **FD SCAN Algorithm:**
   1) Short t transaction on deadline in increasing order. [repeat steps 2 and 3 till no more transactions in queue]
   2) [set start time, end time, seek Time, current head position, total transaction time, turnaround time for all the transactions in the queue]
      a) For first transaction set start time = actual arrival time.
      c) For all transactions set the following parameters. Set start time = end time [except first transaction] set current Head position = blocked Accessed
      Set seek time = blocked accessed – current head position
      Set total transaction time = seek time = transmission time
      Set end time = start time + total transaction time set turn around time = end time – actual arrival time
   3) [check transaction is miss or hit]
      If (end Time > deadline) Set successful = false
      Set successful = false
      Set end time =start Time
Else
Ser successful = true
End if
4) Exit

**P-SCAN Algorithm:**
Construct three queue namely MIN [100], MID [100], MAX [100] to store the transaction with minimum, middle or maximum priorities.

[set LOW_DL and UP-DL]
Set LOW_DL = min Deadline
Set UP_DL = max deadline
Repeat steps 4 and 5 till no more transactions
[store the transaction in the corresponding queue i.e. MIN, MID, MAX]
If deadline > (LOW_DL + UP_DL) / 2
MIN[i] = deadline
I = i+1
Else
If deadline < (LOW_DL + UP_DL) / 4
MAX[j] = deadline
J = j+1
Else
MID[k] = deadline
End if
[set start time, end time, seek time, current head position, total transaction time, turn around time for all the transactions in the MAX queue]
1) [set start time, end time, seek time, current head position, total transaction time, turn around time for all the transactions in MID queue]
b) for all transactions set the following parameters set start Time = end time [except first transaction]
Set current Head Position = Blocked Accessed
Set seek Time = blocked Accessed – current Head position
Set total transaction time = seek Time + transmission time
Set end Time = start Time + total Transaction Time set
turn Around Time = end Time – actual Arrival Time

3) [check transaction is miss or hit in MAX queue]
If (end Time > deadline)
Set successful = start time
Else
Set successful = true
End if
4) [check transaction is miss or hit in MID queue]
If (end Time > deadline)
Set successful = true
End if
5) [check transaction is miss or hit in MIN queue]
If (end time > deadline)
Set successful = false
Else
Set successful = true
End if
6) Exit

3. **SSEDO Algorithm:**
1) Sort t transaction on deadline in increasing order.
2) [set state Time, end Time, seek Time, current head Position, total Transaction Time, turn Around Time
fir the transactions with minimum deadline in the queue]
Set start Time = actual Arrival Time
Set current head Position = blocked Accessed
Set seek time = blocked Accessed – current head position
Set total Transaction Time = seek Time + transmission Time
Set end Time = start Time + total Transaction Time set
Turn Around time = end Time – actual arrival Time
3) [find transaction with seek time within (TV) threshold]
4) For all the transactions in the queue with seek time within threshold (TV)
   If ((block accessed – current head position) <= tv)
      Set current Head position = blocked Accessed
      Set seek Time – current head Position
      Set total transaction Tie = seek Time = transmission Time
5) Go to step 3
6) [check transaction is miss or hit]
   If (end time > dead line)
      Set successful = false
   Else
      Set successful = true
   End if
7) Exit

4. SSEDV Algorithm:
1) Sort transaction on deadline in increasing order.
2) [set start Time, end time, seek time, current head position, total transaction time, turnaround time for the transactions with minimum deadline in the queue]
Set start time = actual arrival time
Set current head position = blocked accessed
Set seek time = blocked accessed – current head position
Set total transaction time = seek time + transmission time
Set end time around time = end time – actual arrival time
3) [find transaction with seek time within (tv) threshold]
   For all the transactions in the queue with seek tie within threshold (tv)
   If ((block accessed – current head position) <= tv)
      Set successful = true
   Else
      Set successful = false
   End if

CONCLUSION:
After developing the Algorithms for real-time disk scheduling problem it is observed that in EDF transactions are ordered according to deadline and the request with earliest deadline is services first. Priority Scan divides all the request in the I/O queue the scan algorithm then serves any request that is passes in the current served priority level until there are no more request in that direction. In FD-SCAN, the track location of the request with earliest feasible deadline is used to determine the scan direction. In the SSEDO algorithm, the scheduler uses the ordering information of request deadlines,
whereas SSEDV use the difference between deadlines if successive requests in the window.

The results of the comparison shows that, performance of SSEDV is better than SSEDO, since the SSEDV uses more timing information than the SSEDO for decision making. P-SCAN and FD-SCAN perform essentially at the same level, with one better at high load cases, but worse for low load cases. The EDF algorithm is good when the system is lightly loaded, but it degenerates as soon as load increases.
