Abstract: - Structural failure in asphalt pavements is happened primarily due to fatigue and rutting. To measure rutting performance, the critical vertical compressive strain (\( \varepsilon_c \)) at the top of subgrade layer are normally used in the mechanistic-empirical (M-E) pavement design process. However, the computation of \( \varepsilon_c \) in a 3-D multilayered pavement structure with distributed loading is a complex phenomenon. This paper attempts to present simple predictive strain transfer function for estimation of \( \varepsilon_c \), considering 3-D analysis of asphalt pavements. The developed transfer function is validated and found adequate in prediction of \( \varepsilon_c \). Degree of accuracy has also been justified statistically. ABAQUS software is used for analysis of pavement structures.

Keywords: - Asphalt pavement, strain, rutting.

I. INTRODUCTION

Mechanistic-Empirical (M-E) design method is being popularly used for structural design of asphalt pavements (AI, 1999; Austroads, 2004; French, 1997; IRC, 2012; Shell, 1978; TRL, 1993; NCHRP, 2004). Traditionally, the mechanistic parameter like critical vertical compressive strain (\( \varepsilon_c \)) at the top of subgrade layer is correlated with rutting performance in asphalt pavements. However, the accurate estimation of \( \varepsilon_c \) in pavement structure is a complex task. Primary reasons of such complexities are multilayered and its interaction between the layers, visco-elastic behavior of asphalt material, structural boundary conditions, axle and wheel configurations, environmental factors etc. To avoid these, certain simplifications and approximations are made and the solutions are obtained through numerical analysis. Software such as ABAQUS, ANSYS, KENPAVE, FPAV etc are used by various researchers (Chandra et al., 2008; Das and Pandey, 1999; Hadi and Bodhinayake, 2003; Kuo and Chou, 2004; Helwany et al., 1998; Lacey et al., 2007; Rahman et al., 2011) for pavement analysis. It requires high technical skill, expertise manpower and computing facility as well. However, a designer or a state department may not be comfortable for such infrastructures and efforts. This paper attempts to present simple expressions for strain calculation in multilayered asphalt pavements, including its acceptability and validation. Finite element method (FEM) based software ‘ABAQUS’ is adopted for analysis of multilayered pavement sections.

II. BACKGROUND

Current practice of asphalt pavements design, popularly known as Mechanistic-Empirical (M-E) design method is followed in various guidelines (AI, 1999; Austroads, 1992; French, 1997; IRC, 2012; Shell, 1978; TRL, 1993; NCHRP, 2004). Fatigue and rutting are considered as two primary modes of structural failures. In general, the failure criteria adopted as 20% of surface cracks area in case of fatigue and 20mm of rut depth in case of rutting failure. The numbers of load repetitions till failure is recorded as pavement life. Rutting life (\( N_r \)) of the pavement are empirically correlated with the critical strain parameter of the section. A general form of rutting equations may be expressed as given in Equations (1).

\[
N_r = c_1 \times \left( \frac{1}{\varepsilon_c} \right)^{c_2} 
\]

(1)

where, \( N_r \) is the rutting life; \( \varepsilon_c \) is the initial critical vertical compressive strain at the top of subgrade layer; and, \( c_1 \) and \( c_2 \) are regression constants. Different literatures suggest different values for these parameters. Some of them are listed in Table 1.

It may be mentioned that \( N_t \) and \( \varepsilon_z \) shall be in respect of same loading conditions (say, standard axle load of 80kN). Replacing \( N_t \) by the total number of traffic repetitions to be sustained during the design life, the maximum allowable \( \varepsilon_z \) value can be determined from Equation (1). Accordingly, comparing these strains values with the computed \( \varepsilon_z \) as obtained from structural analysis, the thicknesses of the design layer(s) can be decided iteratively.

To calculate \( \varepsilon_z \) value, it needs to solve 3-D equilibrium and compatibility equations, along with adequate boundary conditions. Approximate solution can be obtained through numerical analysis. FEM is one of the most powerful numerical techniques, which is widely used for such solutions. FEM based software ‘ABAQUS’ has been adopted by various researchers (Hadi and Bodhinayake, 2003; Kuo and Chou, 2004; Helwany et al., 1998; Lacey et al., 2007; Rahman et al., 2011) for numerical analysis of pavement structures. In the present work also, ABAQUS is used to model and analyze the asphalt pavements, and it is discussed in the next section.

III. MODELING OF PAVEMENT STRUCTURE

Normally, an asphalt pavement structure contains 3 to 4 number of load bearing layers. In this study, a 3-layered and a 4-layered pavement has been modeled as 3-D nonlinear elastic structure with finite boundaries. A 3-layered pavement section is shown in Figure 1. FEM based analysis of the pavement is carried out in the ABAQUS environment. Eight noded linear brick elements with reduce integration (C3D8R) is used in analysis, which considers only one integration point at the middle. This element has ability to reduce the computational effort without significant affect on the accuracy. Each element is considered with three degrees of freedom (i.e. displacement in X, Y and Z -directions). Pavement section of 3.5mx10m with end conditions of zero displacement in transverse (-X) and longitudinal (-Y) directions, and fixed end at the bottom of subgrade are used, including rough interface between two layers. A fine mesh of 4.9cmx7.2cm for asphalt layer, and coarse mesh of 9.8cmx14.24cm for granular and subgrade layers are chosen. This is depicted in Figure 1. The analysis of pavement structures has been discussed in the next section.

IV. PAVEMENT ANALYSIS AND MODELS DEVELOPMENT

In M-E pavement design process, the rutting performance is predicted based on initial critical vertical compressive strain (\( \varepsilon_z \)) at the top of subgrade. Table 2 shows the layers information for a 3-layered pavement section. To represent the different cases, possible ranges of each parameter has been considered as shown in the table. Poisson’s ratio is taken as constant due to negligible effect (Huang, 2004). A uniformly distributed standard dual wheel load of 20kN each with tyre pressure of 0.7MPa over its contact area has been adopted for all the cases.

For different combinations of layers input as given in Table 2, the strain parameter (\( \varepsilon_z \)) are computed through ABAQUS. Figure 2 shows the strains contour in one case obtained from the ABAQUS analysis. The variations of \( \varepsilon_z \) with asphalt modulus (\( E_1 \)) is shown in Figure 3. Negative value indicates compression. Similarly, \( \varepsilon_z \) variations with other variable parameters are also presented in Figures (4) – (7).

From Figures (3) – (7), it is observed that $\varepsilon_z$ parameter is closely correlated with the independent parameters. Combining all the independent variables together, the nonlinear multivariable best fit curves for a 3-layered pavement structure are derived using EViews as given in Equation (2).

$$
\varepsilon_z = r_1 + r_2 \ln(E_1) + r_3 \ln(E_2) + r_4 \ln(E_3) + \\
r_5 \ln(h_1) + r_6 \ln(h_2)
$$

(2)

where, $E_1$, $E_2$ and $E_3$ are the modulii of asphalt, granular and subgrade layer respectively in MPa; $h_1$ and $h_2$ are the thicknesses of asphalt and granular layer respectively in cm; and $r_i$ are the model parameters. The $r_i$ parameters show reasonable contribution to $\varepsilon_z$. This is what it is expected also.

</tbody>
</table>

Equation (2) is obtained statistically and therefore, it is essential to justify its confidence level in prediction. To this effect and to examine the adequacy of model, various statistical parameters of the strain model are evaluated and are tabulated in Table 4. As seen in the table, it may be concluded that the independent parameter posses good correlation with the dependent parameters (i.e. $E_z$) and may be acceptable.

In a similar way, the strain transfer functions are also developed for 4-layered pavement structures viz., asphalt, granular base, granular sub-base and subgrade layers, and found that the strain parameter ($E_z$) is closely correlated with the structural input parameters. The nonlinear multivariable best fit curves for $E_z$ in 4-layered pavement structure is derived as given in Equation (3).

Further, it is attempted to validate the developed models using separate sets of input data, through ABAQUS and KENPAVE analysis as well. This is illustrated in the next section.

V. VALIDATION

In order to validate the statistical strains transfer functions, different asphalt pavement sections are analyzed considering separate sets of input data. The strain ($E_z$) values are evaluated using both ABAQUS and KENPAVE analysis program. The comparison of $E_z$ values calculated from pavement analysis and the developed strain models are shown in Figure 8. To compare the strain transfer function in terms of the rutting life ($N_r$) prediction, a comparison of $N_r$ values in million standard axles (msa) are presented in Figure 9. Regression constants of the rutting equations are adopted as per TRL models (Huang, 2004). Thus, from Figure 8 or Figure 9 it may be concluded that the model predictions are sufficiently good as that of ABAQUS or KENPAVE analysis programs.
VI. CONCLUSIONS

Simple strain transfer functions for vertical compressive strain ($\varepsilon_z$) in asphalt pavement is developed for 3 layered and 4-layered pavement structures and presented in the paper. The proposed $\varepsilon_z$ functions are validated and found adequate in prediction. Statistically also, these transfer functions are tested and found confident. Thus, the proposed strain models can easily be adopted for rutting life estimation in the pavement design process, and can be avoided complex analysis and computational effort. Also, to incorporate the reliability or probability in pavement design, one can easily know the distribution of $\varepsilon_z$ for any given distributions of their input parameters. For example, the $\varepsilon_z$ parameter would follow normal distribution, in case the inputs $E_i$ and $h_i$ in strain functions (Equations (2)-(3)) are log-normally distributed.

Towards M-E design of asphalt pavements, this work focuses on establishing an acceptable statistical correlation between the strain parameter ($\varepsilon_z$) and layers information in 3-layered and 4-layered pavement structures. However, they have few limitations like the effect of moving loads, visco-elastic behavior etc are not accounted and are recommended for further studies.
